

Received a red rice from a customer for repair **Note 9**The failure phenomenon is to shut down and restart from time to time. Sometimes I can't get in to the system. After the screen is lit, it restarts. You can see the current when the machine is disassembled and powered. It jumps normally, and the screen is also turned on normally. It is suspected that there is something wrong with the power-on button, so I test it. After a look at the resistance value of the power-on button, about **4K** Left and right, under normal circumstances, turn on the button There should be no resistance value when it is not pressed, so the small switch on the power is pried open with a blade. I found that the concave iron sheet used for the switch had turned black. I checked the information of Xinzhi Manufacturing and found that it was turned on. The machine lowers the power management chip by turning on the key. **PWRKEY** This signal is true. Now, this model of machine should have a large current when it is pulled down. Every time the boot button is pressed. There is a slight ignition phenomenon from time to time. Over time, it is easy to cause a slight short circuit of the boot button. Then there is an irregular restart failure. Peers can refer to such problems for reference.
